

## Practical - 1

Aim: To search a number from the list using linear unsorted.

Theory: The process of identifying or finding a particular record is called searching.

There are two types of search.

- ① Linear search
- ② Binary search.

Linear search is further classified as:

- a) Sorted
- b) Unsorted

Unsorted linear search:

Linear search also known as sequential search is a process that checks every element in the list sequentially until the desired element is found. When the element is to be searched are not specifically arranged

in ascending or descending order. They are arranged in random manner.

Search called as unsorted linear search or unsorted or random search.

The unsorted linear search method

```
found=False  
A=[59,70,61,77,54]  
print("Sakshi DilipKamthe \n RollNo. 1770")  
search=int(input("Search the NO.:"))  
for i in range(len(A)):  
    if(search==A[i]):  
        print("No. Is Found At:",i,"index")  
        found=True  
        break;  
if (found==False):  
    print("Not Found")
```

```
Python 3.7.4 (tags/v3.7.4:9追寻, 2019-07-11 15:05:31 +0200, 2019-07-11 15:05:31 +0200) [MSC v.1910 32 bit (Intel)] on win32

>>> |
```

Unsorted linear search

- ① the data is entered in random manner
- ② user needs to specify the element to be searched in the entered list.
- ③ check the condition that whether the entered number matches or not, if matches then display the location of the element in as data is stored from location 1 to 10.
- ④ if all elements are checked & one by one & element not found then a message number not found.

~~We can't guarantee that the element will be present in the list at all times~~

→ In unsorted list we don't know which element is present in which location.

→ In sorted list we can search for an element in O(n) time complexity.

→ In unsorted list we can search for an element in O(n) time complexity.

→ In unsorted list we can search for an element in O(n) time complexity.

→ In unsorted list we can search for an element in O(n) time complexity.

→ In unsorted list we can search for an element in O(n) time complexity.

## Practical - 2

Aim: To search a number from the list using linear sorted.

Theory: searching & sorting are different modes or types of data structures. sorting - To basically sort the inputs data in ascending or descending manner. searching - To search elements in the same manner.

In searching the two in linear sorted search, the data is arranged in ascending or descending order. that is all what is meant by searching through 'sorted' that is will arrange data.

### Sorted Linear Search

- ① The user is supposed to enter data in sorted manner.
- ② User has to give an element for searching through sorted list.
- ③ If element is found display with an update as value is stored from location "0".
- ④ If data or element not found print the same.

```
found=False  
print("Sakshi DilipKamthe \n RollNo. 1770")  
A=[59,61,70,77,99]  
search=int(input("Search the No.:"))  
if(search<A[0] or search>A[len(A)-1]):  
    print("Not Found")  
else:  
    for i in range(len(A)):  
        if(search==A[i]):  
            print("No. Is Found At:",i,"index")  
            found=True  
            break;  
    if (found==False):  
        print("Not Found")
```

32

```

>>>
```

In sorted order list of elements user can check the condition that whether the entered number lies from starting point till the last element if not then without any processing user can say number not in the list.

Also in this direct search is a search of smallest step size from first to last element (point) value to check if it is in list or not and provide output like no for 50 & 52 or further with respect to element in list.

The process of binary search is as follows  
1. It starts with left index 0 & right index n-1  
2. If left <= right then calculate mid = (left + right)/2  
3. If target == arr[mid] then return mid  
4. If target < arr[mid] then search in left half  
5. If target > arr[mid] then search in right half  
6. If left > right then return -1

Binary search is also called as divide and conquer algorithm of problem solving and is based on divide and conquer technique.

It is the process of dividing a problem into smaller subproblems of same nature until it reaches the base case.

## Practical-3

Aim: To search a number from the given sorted list using binary search.

Theory: A binary search also known as a half-interval search, is an algorithm used in computer science to locate a specified value (Key) within an array for the search to be binary, the array must be sorted in either ascending or descending order.

Each step of algorithm a partition is made & procedure branches into one of the two directions specifically the Key value is less + compared to the middle elements of the array. If the Key value is less than or greater than this middle element, the algorithm know which half of the array he went to searching in because the array is sorted.

This process is repeated on progressively smaller segment of the array until the value is located. Because each step in the algorithm divides the array size half a binary search will complete successfully in logarithmic.

```

A=[59,61,70,77,99]
print("Sakshi DilipKamthe \n RollNo. 1770")
search=int(input("Search the No.:"))
l=0
r=len(A)-1
while True:
    m=(l+r)//2
    if(l>r):
        print("Not Found")
        break;
    if(search==A[m]):
        print("Number Is Found At:",m,"index")
        break;
    else:
        if(search<A[m]):
            r=m-1
        else:
            l=m+1

```

34

```

            print("data=",k)  
            self.tos=self.tos-1
```

## Practical-4.

AIM:- To demonstrate the use of stack.

THEORY:- In computer science, a stack is an abstract data type that serves as a collection of elements with two principal operations Push, which adds an element to the collection, and Pop, which removes the most recently added element that was not yet removed. The order may be LIFO (last in first out) or FILO (first in last out). Three basic operations are performed in the stack.

- \* POP: Removes an item from the stack. The items are popped in the order in which they are pushed. If the stack is empty, then it is said to be an underflow condition.
- \* PUSH: Adds an item in the stack. If full then it is said to be overflow condition.
- \* PEEK OR TOP: Returns top element of stack.
- \* IS EMPTY: Returns true if stack is empty else false.

Pop  
data

stack

Last-in - First-out

Let us

see how

```
s.push(30)  
s.push(40)  
s.push(50)  
s.push(60)  
s.push(70)  
s.push(80)  
s.pop()  
s.pop()  
s.pop()  
s.pop()  
s.pop()  
s.pop()  
s.pop()
```

**OUTPUT:**

Sakshi

W 1770

Stack is full

data= 70

data= 60

data= 50

data= 40

data= 30s

data= 20

data= 10

stack empty

### SOURCE CODE:

```
print("Sakshi \n 1770")  
  
class Queue:  
    global r  
    global f  
  
    def __init__(self):  
        self.r=0  
        self.f=0  
        self.l=[0,0,0,0,0]  
  
    def add(self,data):  
        n=len(self.l)  
        if (self.r<n-1):  
            self.l[self.r]=data  
            self.r=self.r+1  
        else:  
            print("Queue is full")  
  
    def remove(self):  
        n=len(self.l)  
        if (self.f<n-1):  
            print(self.l[self.f])  
            self.f=self.f+1  
        else:  
            print("Queue is empty")
```

∴ To demonstrate queue add and delete

THEORY: Queue is a linear data structure where the first element is inserted from one end called REAR and deleted from the other end called as FRONT.

Front Points to the beginning of the queue & Rear Points to the end of the queue.

Queue follows the FIFO (First-in-first-out) structure.

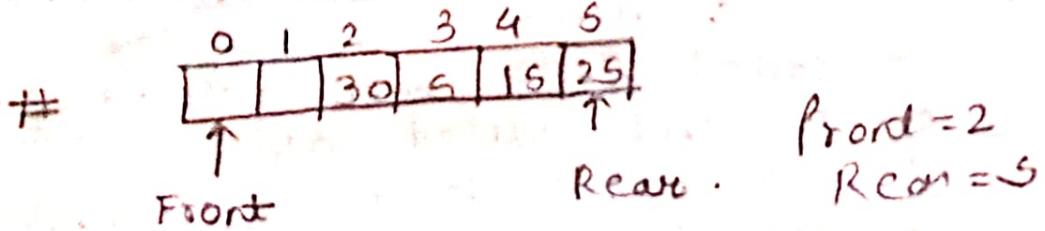

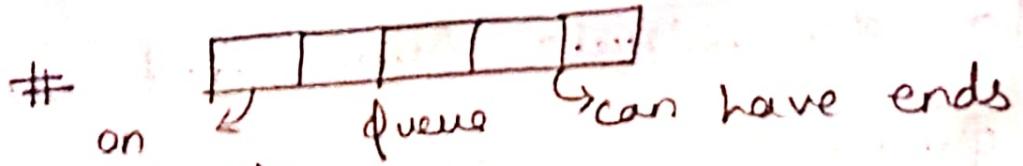

According to its FIFO structure element inserted first will also be removed first. In a queue, one end is always used to insert data (enqueue) & the other is used to delete data (dequeue) because queue is open at both of its ends.

enqueue () can be termed as add () in queue i.e. adding a element in queue.

Dequeue () can be termed as delete or Remove i.e. deleting or removing of element. Front is used to get the front data item from a queue.

Rear is used to get the last item from a queue.

q.remove()

OUTPUT:

Sakshi

1770

Queue is full

30  
40

50

60

70

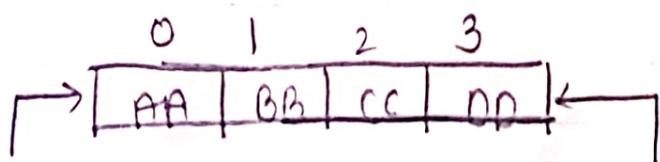

Queue is empty

### SOURCE CODE:

```
print("Sakshi \n 1770")
class Queue:
    global r
    global f
    def __init__(self):
        self.r=0
        self.f=0
        self.l=[0,0,0,0,0,0]
    def add(self,data):
        n=len(self.l)
        if (self.r<n-1):
            self.l[self.r]=data
            print("data added:",data)
            self.r=self.r+1
        else:
            s=self.r
            self.r=0
            if (self.r<self.f):
                self.l[self.r]=data
                self.r=self.r+1
            else:
                self.r=s
                print("Queue is full")
    def remove(self):
        n=len(self.l)
```

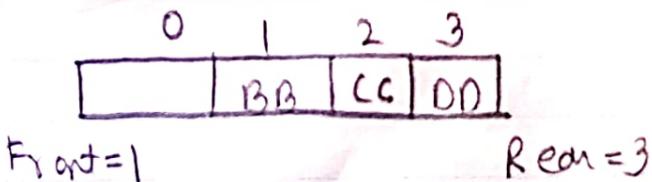

- To demonstrate the use of circular queue
  - The queue that we implement using an array suffers from one limitation. In that implementation there is a possibility that the queue is reported as full, even though in actuality there might be empty slots at the beginning of the queue.
- To overcome this limitation we can implement queue as circular queue. In circular queue we go on adding the element to the queue & reach the end of the array. The next element is stored in the first slot of the array.

Example:

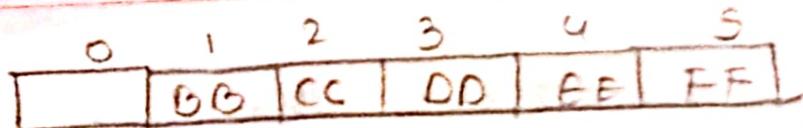

Front = 0

Rear = 3

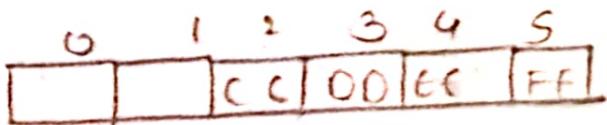

Front = 1

Rear = 3

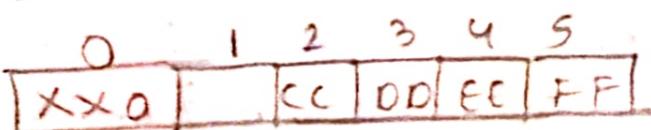

Front = 1

$$\text{Rear} = 5$$

Front = 2

Reactor

$$T \times 0.5 = 2$$

~~rear = 0~~

```
print("Data removed:",self.l[self.f])
self.f=self.f+1
else:
    s=self.f
    self.f=0
    if (self.f<self.r):
        print(self.l[self.f])
        self.f=self.f+1
    else:
        print("Queue is empty")
        self.f=s
q=Queue()
q.add(44)
q.add(55)
q.add(66)
q.add(77)
q.add(88)
q.add(99)
q.remove()
q.add(66)
```

            self.s=newnode
```

## Practical - 8

Aim :- To demonstrate the use of linked list in data structures.

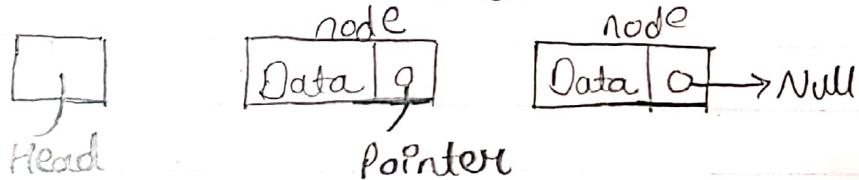

Theory :- A linked list is a sequence of data structures. A linked list is a sequence of links which contains items. Each link contains a connection to another link.

- LINK - Each link of a linked list can store a data called an element.

- NEXT - Each link of a linked list contains a link to the next link called NEXT.

- LINKED - A linked list contains the connection link to the first-link called FIRST.

### LINKED LIST Representation:

## Types of LINKED LIST:

- ↳ Simple
- ↳ Doubly
- ↳ Circular

## BASIC OPERATIONS

- ↳ Insertion
- ↳ Deletion
- ↳ Display
- ↳ search
- ↳ Delete

```
def display(self):  
    head=self.s  
    while head.next!=None:  
        print(head.data)  
        head=head.next  
    print(head.data)  
  
start=linkedl()  
start.addl(50)  
start.addl(60)  
start.addl(70)  
start.addl(80)  
start.addb(40)  
start.addb(30)  
start.addb(20)  
start.display()
```

### SOURCE CODE:

```
print("Sakshi\n1770")  
  
def eva(s):  
    k=s.split()  
    n=len(k)  
    stack=[]  
    for i in range(n):  
        if k[i].isdigit():  
            stack.append(int(k[i]))  
        elif k[i]=='+':  
            a=stack.pop()  
            b=stack.pop()  
            stack.append(int(b)+int(a))  
        elif k[i]=='-':  
            a=stack.pop()  
            b=stack.pop()  
            stack.append(int(b)-int(a))  
        elif k[i]=='*':  
            a=stack.pop()  
            b=stack.pop()  
            stack.append(int(b)*int(a))  
        else:  
            a=stack.pop()  
            b=stack.pop()  
            stack.append(int(b)/int(a))
```

To evaluate Postfix expression using stack

THEORY: Stack is an (ADT) & works on LIFO (last-in first-out) i.e Push & Pop operations. A Postfix expression is a collection of operators & operands in which the operator is placed after the operands.

Steps to be followed:

- 1] Read all the symbols one by one from left to right in the given Postfix expression.
- 2] If the reading symbol is operand then Push it on to the stack.
- 3] If the reading symbol is operator (+, -, \*, /, etc) then Perform TWO Pop operations & store the two Popped operands in two different variables (operand 1 & operand 2). Then Perform reading symbol operation using operand 1 & operand 2 & Push result back on to the stack.
- 4] Finally! Perform a Pop operations & display the Popped value as final result.

value of Postfix expression:

$$S = 12 \ 3 \ 6 \ 4 \ominus + *$$

stack :

4	a
6	b
3	
12	

$$b - a = 6 - 4 = 2 \text{ // store again in stack.}$$

2	a
3	b
12	

$$b + a = 3 + 2 = 5 \text{ // store result in stack.}$$

5	a
12	b

$$b * a = 12 * 5 = 60.$$

```
return stack.pop()  
s="5 3 + 8 2 - *"  
r=eva(s)  
print("The evaluated value is:",r)
```

**OUTPUT:**

Sakshi

1770

The evaluated value is: 48

```
print("sakshi:1770")  
a=[10,8,9,5,3,1,2]  
print(a)  
for i in range(len(a)-1):  
    for j in range(len(a)-1-i):  
        if(a[j]>a[j+1]):  
            t=a[j]  
            a[j]=a[j+1]  
            a[j+1]=t  
print(a)
```

## Practical No. 9

45

Aim: To sort given random data by using bubble sort.

Theory:

SORTING

It is type in which any random data is sorted i.e. arranged in ascending or descending order.

Bubble sort sometimes referred as sinking sort.

It is a simple sorting algorithm that repeatedly steps through the list, compares adjacent elements & swaps them if they are in wrong order.

The pass through the list is repeated until the list is sorted. The algorithm which is a comparison sort is named for the way smaller or larger elements "bubble" to the top of the list. Although the algorithm is simple, it is too as it compares one element checks its condition fails then only swaps otherwise goes on.

## Practical-10

Aim: To evaluate i.e. to sort the given data in Quick sort.

### Theory:

Quicksort is an efficient sorting algorithm type of a divide & conquer algorithm. It picks an element as Pivot & partitions the given array around the picked pivot.

There are many different versions of quick sort that picks Pivot in different ways.

1. Always pick first element as Pivot.
2. Always pick last element as Pivot.
3. Pick a random element as Pivot.
4. Pick median as Pivot.

```
def quicksort(alist):
    quicksortHelper(alist,0,len(alist)-1)

def quicksortHelper(alist,first,last):
    if first<last:
        splitpoint=partition(alist,first,last)
        quicksortHelper(alist,first,splitpoint-1)
        quicksortHelper(alist,splitpoint+1,last)

def partition(alist,first,last):
    pivotvalue=alist[first]
    leftmark=first+1
    rightmark=last
    done=False

    while not done:
        while leftmark<=rightmark and alist[leftmark]<=pivotvalue:
            leftmark=leftmark+1
        while alist[rightmark]>=pivotvalue and rightmark>=leftmark:
            rightmark=rightmark-1
        if rightmark<leftmark:
            done=True
        else:
            temp=alist[leftmark]
            alist[leftmark]=alist[rightmark]
            alist[rightmark]=temp
            temp=alist[first]
            alist[first]=alist[rightmark]
```

```
alist[rightmark]=temp
returnrightmark
alist=[42,54,45,67,89,66,55,80,100]
quicksort(alist)
print(alist)
print("sakshi")
print("roll no:1770")
```

```
python 3.4.3 | Python 3.4.3 | (v3.4.3:9b73fdec601, Feb 24 2015, 22:43:06) [MSC v.1600 32 bit (Intel)] on win32
Type "copyright", "credits" or "license()" for more information.
>>> 
>>> [42, 45, 54, 55, 66, 67, 80, 89, 100]
sakshi
roll no:1770
>>> |
```

The key process is quicksort is Partition().  
Target of Partition is given as array &  
an element  $x$  of array as Pivot, Put  $x$   
as its correct position in sorted array &  
then  $\cancel{x}$  bef. Put all smaller elements (smaller  
than  $x$ ) before  $x$ , & put all greater elements  
(greater than  $x$ ) after  $x$ .

All this should be done in linear time.

## Practical No - 11

Aim To sort given random data by selection sort.

### Theory:

Selection sort is a simple sorting algorithm. It is a sorting algorithm IS an in-place comparison algorithm in which the list is divided into two parts, the sorted part at the left & the unsorted part at the right. Initially, the sorted part is empty and the unsorted part is the entire list.

PROGRAM 11:

```
print("sakshi:1770")
b=[15,14,13,12,11,10]
print(b)

for i in range(len(b)-1):
    for j in range(len(b)-1):
        if (b[j]>b[i+1]):

            t=b[j]

            b[j]=b[i+1]

            b[i+1]=t

print(b)
```

OUTPUT:

The screenshot shows a window titled "Python 2.7.11 Shell". The menu bar includes File, Edit, Shell, Debug, Options, Window, and Help. The main area displays the Python interpreter's prompt and the execution of the provided code. The output shows the initial list [15, 14, 13, 12, 11, 10] followed by the sorted list [10, 11, 12, 13, 14, 15].

### Aim Binary Tree & Traversal.

#### Theory:

A Binary Tree is a special type of tree in which every node or vertex has either one child or two children.

A Binary tree is an important class of a tree data structure in which a node can have at most two children.

Traversal is a process to visit all the nodes of a tree and print their values.

there are 3 ways in which we use to traverse a tree.

(A) inorder.

(B) preorder.

(C) postorder.

(A) inorder

The left - subtree is visited 1<sup>st</sup> then the root & later the right subtree we should always remember that every code way represent a subtree itself output produced is sorted key values in ASCENDING ORDER.

(B) PRE ORDER

The root code is visited 1<sup>st</sup> then the left subtree & finally the right subtree

```
else:  
    if h.r!=None:  
        h=h.r  
    else:  
        h.r=newnode  
        print(newnode.data,"added on right of",h.data)  
        break  
    def preorder(self,start):  
        if start!=None:  
            print(start.data)  
            self.preorder(start.l)  
            self.preorder(start.r)  
    def inorder(self,start):  
        if start!=None:  
            self.inorder(start.l)  
            print(start.data)  
            self.inorder(start.r)  
    def postorder(self,start):  
        if start!=None:  
            self.postorder(start.l)  
            self.postorder(start.r)  
            print(start.data)  
T=Tree()  
T.add(100)  
T.add(35)  
T.add(70)
```

```
T.add(15)
T.add(95)
T.add(97)
print("preorder")
T.preorder(T.root)
print("inorder")
T.inorder(T.root)
print("postorder")
T.postorder(T.root)
```

(c) POST ORDER

The root code is visited last  
left subtree & then the right  
subtree & finally the root code.

Aim Merge sort.Theory:

Merge sort is a sorting technique based on divide & conquer technique with worst case time complexity being  $O(n \log n)$ . It is one of the most respected algorithm.

Merge sort first divides the array into equal halves & then combines them as a sorted manner.

If divides input array into two values, calls itself for the two values & then merge the two sorted values.  
The merge() function is used for merging two values.

```
print("sakshi:1770")

def sort(arr,l,m,r):

    n1=m-l+1

    n2=r-m

    L=[0]*(n1)

    R=[0]*(n2)

    for i in range(0,n1):

        L[i]=arr[l+i]

    for j in range(0,n2):

        R[j]=arr[m+1+j]

    i=0

    j=0

    k=l

    while i<n1 and j<n2:

        if L[i]<=R[j]:

            arr[k]=L[i]

            i+=1

        else:

            arr[k]=R[j]

            j+=1

            k+=1

    while i<n1:

        arr[k]=L[i]

        i+=1

        k+=1

    while j<n2:
```

arr[k]=R[j]  
j+=1  
k+=1  
def mergesort(arr,l,r):  
if l < r:  
m=int((l+(r-1))/2)  
mergesort(arr,l,m)  
mergesort(arr,m+1,r)  
sort(arr,l,m,r)  
arr=[12,23,34,56,78,45,86,98,42]  
print(arr)  
n=len(arr)  
mergesort(arr,0,n-1)  
print(arr)

The Merge Process (arr, L, r, m) is  
the key process that assumes that  
arr [L ... m] and arr [m + 1 ... r] are  
sorted & merges them into one.
